Quantum mechanics defines two classes of particles—bosons and fermions—whose exchange statistics fundamentally dictate quantum dynamics. Here we develop a scheme that uses entanglement to directly observe the correlated detection statistics of any number of fermions in any physical process. This approach relies on sending each of the entangled particles through identical copies of the process and by controlling a single phase parameter in the entangled state, the correlated detection statistics can be continuously tuned between bosonic and fermionic statistics. We implement this scheme via two entangled photons shared across the polarisation modes of a single photonic chip to directly mimic the fermion, boson and intermediate behaviour of two-particles undergoing a continuous time quantum walk. The ability to simulate fermions with photons is likely to have applications for verifying boson scattering and for observing particle correlations in analogue simulation using any physical platform that can prepare the entangled state prescribed here.

A particularly striking departure from classical physics in quantum mechanics is the existence of two fundamental particle classes characterised by their behaviour under pairwise exchange ($a_j^\dagger a_k^\dagger = \pm a_k^\dagger a_j^\dagger$). For example an arbitrary number of bosons (obeying Bose-Einstein statistics: ‘+’) can occupy a single quantum state, leading to bunching¹ and Bose-Einstein condensation; whereas fermions (obeying Fermi-Dirac statistics: ‘−’) are strictly forbidden to occupy the same state via the Pauli-exclusion principle². Behaviour intermediate between bosons and fermions can also be considered; particles confined to two dimensions known as anyons³ are predicted to exhibit intermediate behaviour with fractional exchange statistics ($a_j^\dagger a_k^\dagger = e^{i\phi} a_k^\dagger a_j^\dagger$, $0 < \phi < \pi$)—a concept applied in superconductivity⁴ and used to explain the fractional quantum Hall effect⁵.

Here we show that by tuning one phase parameter, entanglement and a single experimental setup can exactly simulate the measurement statistics of an arbitrary mode transformation A (Fig. 1 (a)) of N identical fermions, bosons or particles with fractional statistics. It is well known that the symmetric and anti-symmetric states $|\psi^\pm\rangle = |H\rangle_1 |V\rangle_2 \pm |V\rangle_1 |H\rangle_2$ of two polarised photons input into a 50% reflectivity beam splitter exhibits fermion-like anti-bunching and boson-like bunching, respectively⁶. Furthermore, intermediate behaviour for a beamsplitter has been observed by controlling a phase to tune between the two Bell states $|\psi^+\rangle$ and $|\psi^-\rangle$ ^{7,8}. It is less widely appreciated that the resulting detection statistics can also be exactly mimicked with two photon path-number entangled NOON states⁹; however this behaviour does not generalise to processes other than beamsplitters, the simplest example being the identity operation for which bunching always occurs regardless of the phase of the NOON state. The approach we present shares N -partite, N -level entanglement, parameterised by phase ϕ , across N copies of A (Fig. 1 (b)).

After presenting the scheme in the case of two particles in an arbitrary linear evolution, we experimentally demonstrate the simulation of arbitrary particle statistics with a complex photonic network—a continuous time quantum walk^{10,11}. We achieve the required entangled state with post-selected polarisation entanglement shared across the TE and TM modes of an evanescently coupled waveguide array. This enables us to directly observe the evolution of symmetric and anti-symmetric two particle wave functions in a coupled oscillator Hamiltonian by switching the phase of the entangled state between 0 and π . Mixed-symmetric quantum walk behaviour is also observed by tuning the entangled state’s phase between 0 and π , corresponding to behaviour intermediate between bosons and fermions. We note the fermion simulation directly maps to the dynamics of two excitations in a spin — $\frac{1}{2}$ chain consisting of ten sites: Using the Jordan-Wigner transformation, excitations correspond to fermion creation operators and the vacuum to the ground state of each spin¹². We finally provide a mathematical demonstration of our scheme in the case of an arbitrary number of particles evolving through any linear

Figure 1 | Simulating quantum interference of quantum particles.

(a) Quantum interference of N identical particles with arbitrary statistics launched into a network described by matrix A leads to quantum correlated detection events at the output. (b) Experimental simulation of quantum interference can be directly achieved by sharing N -partite, N -level entanglement across N copies of A , where the choice of simulated particle statistics is controlled by the phase of initial entanglement.

Hamiltonian. It is important to note that neither the two-particle case, nor the N -particle generalization, require any post-selection and are, in principle, scalable.

Results

Exchange statistics refer to a wave-function acquiring phase ϕ after interchanging two indistinguishable quantum particles. Occupation of labeled modes j are modelled by annihilation operators a_j and creation operators a_j^\dagger that obey the commutation relations

$$a_j^\dagger a_k^\dagger - e^{i\phi} a_k^\dagger a_j^\dagger = 0 \quad (1)$$

$$a_j a_k - e^{i\phi} a_k a_j = 0 \quad (2)$$

$$a_j a_k^\dagger - e^{i\phi} a_k^\dagger a_j = \delta_{j,k} \quad (3)$$

for $j < k$. In three dimensions particles are either bosons ($\phi = 0$) or fermions ($\phi = \pi$) and successive swapping is represented by the permutation group while the correlated detection statistics are associated respectively to the permanent and determinant of a given matrix¹³. In one- and two-dimensions anyons³ can exist where swapping two identical anyons ω times (represented by the braid group) results in the combined wave-function acquiring phase $\phi = \omega\theta$ where $0 < \theta < \pi$ and the positive (or negative) winding number ω keeps track of the number of times two anyons braid in trajectory space with clockwise (or anti-clockwise) orientation⁴.

The quantum correlation function for two identical non-interacting particles (input into j and k of A , and detected at outputs r and q) is given by

$$\Gamma_{r,q}^\phi = |A_{r,j}A_{q,k} + e^{i\phi} A_{r,k}A_{q,j}|^2, \quad (4)$$

for bosons¹⁴ ($\phi = 0$) and fermions¹³ ($\phi = \pi$). Here, the process A is represented by a matrix whose element $A_{r,j}$ is the complex transition amplitude from j to r . Non-classical behaviour is evident in the constructive and destructive interference between typically complex terms inside the $|\cdot|^2$, dictated by $\phi = \omega\theta$. By defining fractional exchange algebra (1–3) for $0 < \theta < \pi$ and some integer winding number ω , we can observe the effect of fractional exchange statistics on quantum interference between two indistinguishable anyons undergoing braiding operations dependent upon A ; Eq. (4) represents the resulting quantum interference between two abelian anyons ($0 < \theta < \pi$) in superposition of braiding ω times and not braiding at all. To see this we define without loss of generality the input labels by $j < k$ and the output labels by $r < q$ and consider two identical anyons created at modes j and k , transformed according to A and detected at modes r and q . Correlated detection at r and q reveals two indistinguishable possibilities that correspond to the two terms in Eq. (4): A maps the anyon at j to mode r and the anyon at k to mode q with amplitude $A_{r,j}A_{q,k}$; or A maps the anyon at j to mode q and the anyon at k to mode r via ω clockwise braids with fractional phase ϕ and amplitude $A_{q,j}A_{r,k}$. From this definition, we use relations (1–3) to derive expression (4) for $0 < \theta < \pi$ and $\phi = \omega\theta$ (see Supplementary Information).

To physically simulate quantum interference given by Eq. (4), we use two copies of A , denoted A^a and A^b , together with bi-partite entanglement of the form $|\psi(\phi)\rangle = (a_j^\dagger b_k^\dagger + e^{i\phi} a_k^\dagger b_j^\dagger)|0\rangle/\sqrt{2}$ where creation operators a_j^\dagger and b_k^\dagger are associated to identical networks A^a and A^b respectively; creation operator sub-indices denote the modes on which the creation operators act. Once $|\psi(\phi)\rangle$ is generated, the class of input entangled particles becomes irrelevant; only one particle is present in each of A^a and A^b , therefore no further quantum interference between particles will occur. This implies application with other quantum platforms, using for example entangled fermions to simulate Bose-Einstein quantum interference. Evolution of the two particle state through the tensor product of transformations is therefore modelled by

$$|\psi(\phi)\rangle \xrightarrow{A^a \otimes A^b} \sum_{s,t} \left(\frac{A_{s,j}^a A_{t,k}^b + e^{i\phi} A_{s,k}^a A_{t,j}^b}{\sqrt{2}} \right) a_s^\dagger b_t^\dagger |0\rangle \quad (5)$$

It follows that correlated detection probability across outputs r of A^a and q of A^b simulates Eq. (4) according to

$$\begin{aligned} P_{r,q}^\phi &= \frac{1}{2} \left| \langle 0 | a_r b_q \sum_{s,t} \left(A_{s,j}^a A_{t,k}^b + e^{i\phi} A_{s,k}^a A_{t,j}^b \right) a_s^\dagger b_t^\dagger | 0 \rangle \right|^2 \\ &= \frac{1}{2} |A_{r,j}^a A_{q,k}^b + e^{i\phi} A_{r,k}^a A_{q,j}^b|^2 \equiv \frac{1}{2} \Gamma_{r,q}^\phi \end{aligned} \quad (6)$$

where the $1/2$ pre-factor is due to normalisation of the initial entanglement. Since the phase of the entangled state can be defined as $\phi = \omega\theta$, this method simulates the interference statistics of two anyons of fractional phase θ that have not braided, with two anyons also characterised by θ that have braided ω times (equivalently anyons that are in a superposition of braiding ω_1 and ω_2 times for $\phi = (\omega_1 - \omega_2)\theta$ —the ideal statistics are the same).

We experimentally simulated Eq. (4) for arbitrary ϕ in a coupled oscillator Hamiltonian equivalent to sharing entanglement across two continuous time quantum walks, realised with arrayed waveguides¹⁰ (see Supplementary Information). We measured the correlations of the polarisation entangled state $(|H\rangle_j |V\rangle_k + e^{i\phi} |V\rangle_j |H\rangle_k)/\sqrt{2}$ shared across two copies of a process A : A^a and A^b , realised as the TE

and TM modes of a waveguide array fabricated in silicon oxynitride (SiO_xN_y) (Fig. 2 (b), see also Methods). The waveguides and butt-coupled polarisation maintaining fibres (PMFs) are birefringent to ensure negligible cross-talk between horizontal and vertical polarisations. Detection statistics of the output photons in the $\{|H\rangle, |V\rangle\}$ basis were analysed using polarising beam splitters (PBS) and pairs of multi-mode fibre coupled avalanche photo-diode single photon counting modules (SPCM) (Fig. 2 (c)). By inputting the state $(|H\rangle_j + |V\rangle_j)(|H\rangle_k + e^{-i\phi}|V\rangle_k)/2$ and detecting one $|H\rangle$ photon and one $|V\rangle$ photon at any pair of outputs of A^a and A^b we post-selected the input state $(|H\rangle_j|V\rangle_k + e^{i(\phi+\epsilon)}|V\rangle_j|H\rangle_k)/\sqrt{2}$, with a measurable phase off-set ϵ (from birefringence of PMF and the waveguide circuit). This phase ϵ was compensated using a polarisation phase rotation (Fig. 2 (a)). Note that because of this compensation, the approach described is immune to birefringence of the 2 m PMF and input waveguides.

We measured two sets of correlation matrices for two different inputs: immediate neighbouring waveguides in the centre of the array $(j, k) = (-1, 0)$ (Fig. 3); and next but one neighbouring waveguides $(j, k) = (-1, 1)$, with vacuum input in waveguide 0 (Fig. 4). Each $P_{r,q}^\phi$ entry is the probability to detect a horizontal and vertical polarised photon at outputs r and q , respectively. Five cases are shown for $\phi = 0, \pi/4, \pi/2, 3\pi/4, \pi$ (left: (a), (c), (e), (g), (i)). The corresponding ideal correlation matrices given by $\Gamma_{r,q}^\phi$ in Eq. (4) are also plotted (right: (b), (d), (f), (h), (j)). For the $(j, k) = (-1, 0)$ input (Fig. 3) we observe the expected bunching behaviour of bosons for $\phi = 0$ which is contrasted with the observation of the Pauli-exclusion in the diagonal elements of the matrices for $\phi = \pi$. We note that a form of exclusion on the diagonal entries $P_{r,r}^\phi$ would also occur for experiments with hard core bosons, but the remaining correlation

matrix would still be dependent upon Bose-Einstein exchange statistics. The spectrum of phase $0 < \phi < \pi$ exhibits a variable Pauli-exclusion and a continuous transition between simulation of Bose-Einstein and Fermi-Dirac quantum interference. In the bosonic case, we observe a less pronounced bunching behaviour for the $(j, k) = (-1, 1)$ input (Fig. 4 (a)) than for the $(j, k) = (-1, 0)$ input (Fig. 3 (a)), as expected¹⁴. This behaviour is inverted in the fermionic case, since the particles tend to propagate to the same peak of the walk (while still not occupying the same waveguide) for the $(j, k) = (-1, 1)$ input (Fig. 4 (i)), and tend to propagate in different peaks for the $(j, k) = (-1, 0)$ input (Fig. 3 (i)). This is the result of the different phases in the Hamiltonian that describes the quantum walk evolution.

Agreement between the ideal implementation of our scheme, with perfect realisations of A^a and A^b , and the data in Figs. 3,4 is quantified in Table I using the similarity S between the ideal correlation matrix Γ^ϕ and the measured distribution of detection statistics P^ϕ : $S = \left(\sum_{r,q} \sqrt{\Gamma_{r,q}^\phi P_{r,q}^\phi} \right)^2 / \sum_{r,q} \Gamma_{r,q}^\phi \sum_{r,q} P_{r,q}^\phi$, a generalisation of the average (classical) fidelity between two probability distributions that ranges from 0% (anti-correlated distributions) to 100% for complete agreement. We also calculated S when we deliberately made the photons distinguishable by temporally delaying one with respect to the other. This enabled physical simulation of the classical correlations $\Gamma^C = |A_{r,j}A_{q,k}|^2 + |A_{r,k}A_{q,j}|^2$ that are independent of particle statistics. For these measurements, we found agreement with the ideal model of $S = 97.4 \pm 0.7\%$ and $S = 97.5 \pm 0.6\%$ for inputs $(-1, 0)$ and $(-1, 1)$ respectively. These data indicate that A^a and A^b are near identical while keeping crosstalk between horizontal and vertical polarisation to a minimum. While non-unit similarity ($S = 100\%$) in Table I is attributed to non-perfect entanglement generation, the high level of agreement between the ideal and measured

Figure 2 | Experimental setup. (a) The parametric down-conversion based photon pair source with quarter-waveplates (QWP), half-waveplates (HWP) and a polarisation beamsplitter cube (PBS) used as a polariser, to control the initial state before input into the chip. Down conversion in the nonlinear bismuth borate (BiBO) crystal yields degenerate photon pairs (808 nm, filtered with 2 nm full width, half maximum interference filters, IF) collected into polarisation maintaining fibres (PMF). See Methods for further details. (b) Two copies of the quantum walk unitary are realised by accessing the TE and TM modes of the polarisation preserving waveguide array. Three input modes of the array are used in the experiment $(-1, 0, 1)$ accessed via waveguide bends that fan to a pitch of $250 \mu\text{m}$ and butt-coupled to an array of PMF. Output is accessed via a fan of waveguide from the coupling region to a pitch of $125 \mu\text{m}$. See Methods for details. (c) The detection scheme consists of five PBS and single photon counting module (SPCM) pairs. PMF coupled to the chip launch the output photons onto each PBS which separates TE and TM modes guided in the waveguide. The two outputs of each PBS are collected into multi-mode fibre (MMF) coupled to SPCMs for correlated detection via counting electronics.

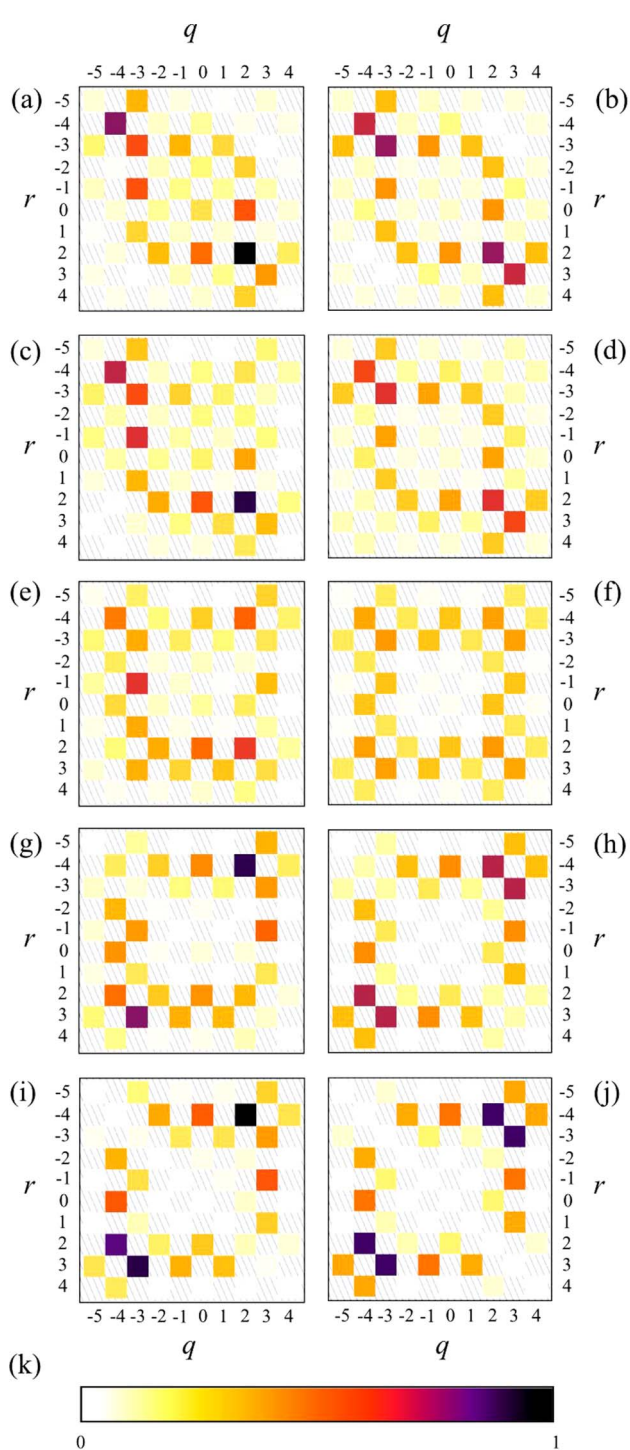

Figure 3 | Experimental simulation of particle statistics correlation functions for input $(-1, 0)$. Experimental correlation matrices (left: a,c,e,g,i) for simulating quantum interference of non-interacting particle pairs with five different particle statistics. Ideal correlation matrices for this experiment are plotted (right: b,d,f,h,j) using Eq. (4). The data ranges from corresponding to Bose-Einstein statistics ($\phi = 0$, (a,b)) through fractional statistics ($\phi = \pi/4$, (c,d); $\phi = \pi/2$, (e,f); $\phi = 3\pi/4$, (g,h)) to Fermi-Dirac statistics ($\phi = \pi$, (i,j)). (k) The correlation matrices are displayed as normalised probability distributions with white for probability $P_{r,q}^\phi = 0$ and black for $P_{r,q}^\phi = 1$. Solid coloured squares represent measured correlations, hatched squares correspond to coincidences that cannot be measured due to mis-match between fibre array separation and waveguide pitch (see Methods). Coincidence rates are corrected for relative detection efficiency.

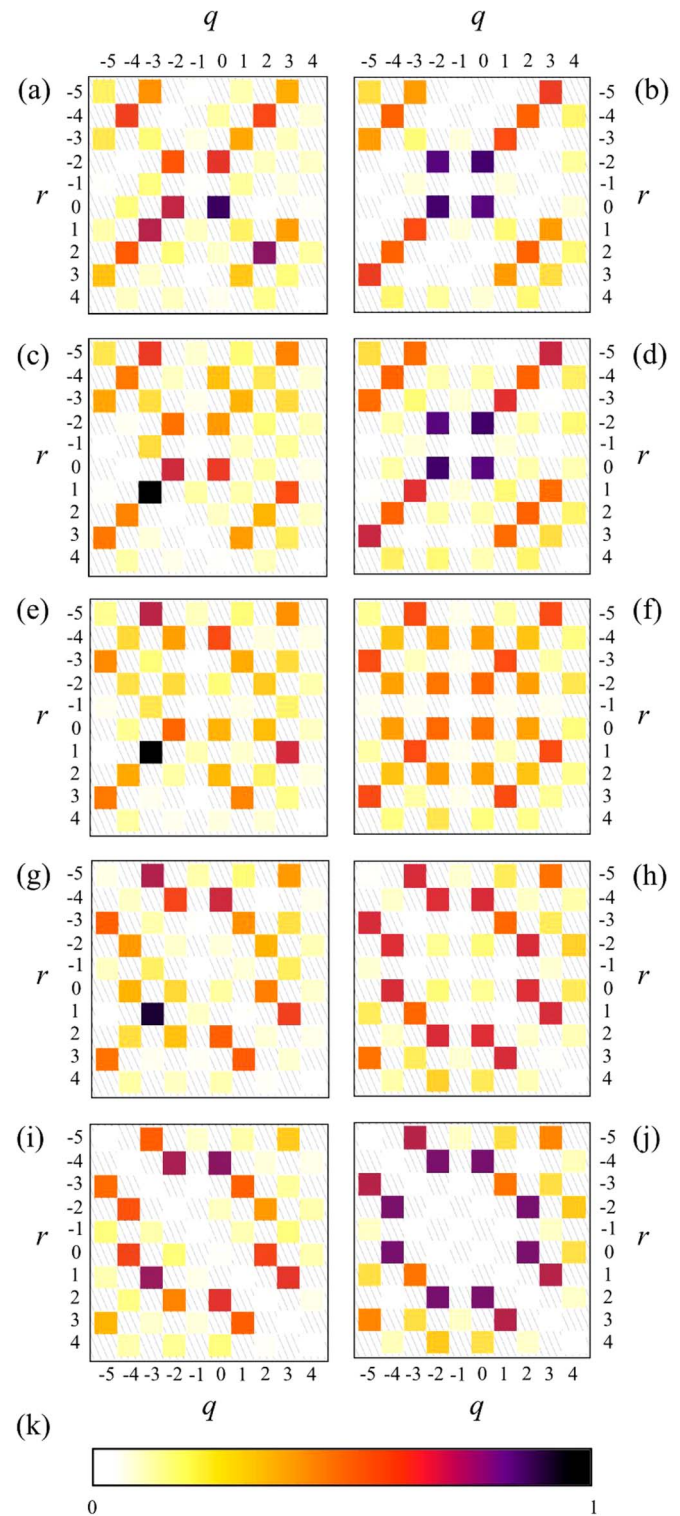

Figure 4 | Experimental simulation of particle statistics correlation functions for input $(-1, 1)$ with data laid out as for Fig. 3.

cases indicates accurate quantum simulation of arbitrary quantum interference in a uniform coupled oscillator Hamiltonian.

Using multi-partite entanglement allows simulation of quantum interference of an arbitrary number N of identical non-interacting particles. N indistinguishable particles with exchange statistics ϕ , subjected to mode transformation A at inputs $\vec{v} = \{v_1, v_2, \dots, v_N\}$, are correlated due to quantum interference across outputs $\vec{\mu} = \{\mu_1, \mu_2, \dots, \mu_N\}$ according to

Table 1 | Similarity S for each experimental simulation of particle quantum interference with parameter ϕ , for input $(-1, 0)$ given in Fig. 3 and input $(-1, 1)$ given in Fig. 4

| Phase, ϕ | S (%) for input $(-1, 0)$ | S (%) for input $(-1, 1)$ |
|---------------|-----------------------------|-----------------------------|
| 0 | 95.8 ± 0.6 | 90.9 ± 0.5 |
| $\pi/4$ | 95.2 ± 0.7 | 93.6 ± 0.6 |
| $\pi/2$ | 94.1 ± 0.7 | 93.5 ± 0.6 |
| $3\pi/4$ | 94.4 ± 0.7 | 94.1 ± 0.6 |
| π | 91.6 ± 0.7 | 92.7 ± 0.6 |

$$\Gamma_{\vec{\mu}}^{\phi} = \left| \sum_{\sigma_v \in S_N} e^{i\tau(\sigma_v)\phi} \prod_{j=1}^N A_{\mu_j, \sigma_{v_j}} \right|^2, \quad (7)$$

where σ_v is an element of the permutation group S_N acting on \vec{v} and $\tau(\sigma_v)$ is the minimum number of neighbouring swaps that maps σ_v to \vec{v} ; σ_{v_j} denotes the element j of σ_v . For $\phi = 0$ and $\phi = \pi$, Eq. (7) is the modulus-square of the permanent and determinant respectively of an $N \times N$ subset of A . For $0 < \phi < \pi$ Eq. (7)—which is the modulus-square of the immanent of the $N \times N$ subset of A —is derived in the Supplementary Information. The multi-particle correlation function Eq. (7) is simulated by subjecting the generalised N -partite, N -level entangled state

$$\frac{1}{\sqrt{N!}} \sum_{\sigma_v \in S_N} e^{i\tau(\sigma_v)\phi} \prod_{j=1}^N a_{\sigma_{v_j}}^{(j)\dagger} |0\rangle, \quad (8)$$

to N copies of A such that one particle $a^{(j)\dagger}$ is launched into each copy $A^{(j)}$. For example, for inputs j, k, l and $N = 3$, the required entangled input state is equivalent to three entangled qutrits, shared across three copies of A denoted A^a, A^b and A^c :

$$\frac{1}{\sqrt{6}} \left(a_j^\dagger b_k^\dagger c_l^\dagger + e^{i\phi} a_j^\dagger b_l^\dagger c_k^\dagger + e^{i\phi} a_k^\dagger b_j^\dagger c_l^\dagger + e^{i2\phi} a_k^\dagger b_l^\dagger c_j^\dagger + e^{i2\phi} a_l^\dagger b_j^\dagger c_k^\dagger + e^{i3\phi} a_l^\dagger b_k^\dagger c_j^\dagger \right) |0\rangle \quad (9)$$

N -fold coincidence detection across outputs μ_j of $A^{(j)}$ equals $\frac{1}{N!} \Gamma_{\vec{\mu}}^{\phi}$. Note as for the case with two particles, the $1/N!$ pre-factor can be canceled by considering all $N!$ permutations of the outputs, therefore directly simulating quantum interference of N bosons ($\phi = 0$) or N fermions ($\phi = \pi$). For example, in the 2-particle case, the $1/2$ pre-factor in Eq. (6) is canceled by summing both the detection outputs of a particle at r on A^a, q on A^b and at r on A^b, q on A^a . All other values of ϕ allow continuous transition between Fermi and Bose quantum interference. Note that the approach of initialising the simulation with a pre-symmetrized (or pre-antisymmetrized) state is in the spirit of first quantised quantum simulation¹⁵, for which quantum algorithms have been designed to efficiently generate the required states^{16,17} (see Supplementary Information). In a photonic realization of the proposed scheme, the required N -particle entangled state can be generated using additional photons and feedforward to implement quantum gates following the KLM scheme¹⁸.

Discussion

Correlations resulting from quantum interference of multiple indistinguishable non-interacting bosons in large linear optical circuits cannot be efficiently simulated with classical computers^{19–21}. Large scale repeated quantum interference is achievable with photons in waveguides^{11,22–24}, which is likely to provide the platform for the realisation of such a boson scattering device, to realise an engineered system that can outperform the limits of classical computation. A major issue will be verifying boson scattering correlations that exceed the capabilities of conventional computers. In contrast, the

analogous situation for non-interacting fermions is efficient with classical computers (currently it is not as straightforward to perform quantum interference of fermions^{2,25} as it is with photons in integrated optics). The ability to tune continuously between tractable and intractable phenomena with a single setup could be essential for verification of bosonic scattering.

Other possible applications for simulating particle statistics with photonics include preparing appropriately symmetrized states in quantum chemistry simulations¹⁵ and combinatorics, where exchange statistics have been shown to alter mathematical graph structure²⁶—three-dimensional waveguide architectures²⁷ may be important here. Our simulation of arbitrary fractional exchange statistics also provides a novel method to study fractional quantum interference phenomena²⁸; whether our approach can be used in the context of topological fault tolerant quantum computation with photons^{29,30} is an open question.

The method we report can be directly applied to any quantum process realisable with linear optics³¹ and is not reliant on using polarisation—the entangled state could be encoded in time-bin or interferometrically stable path with reconfigurable waveguide circuits³². In order to introduce interactions between simulated particles, it may be possible to use effective non-linearities using auxiliary photons^{18,33}. In the long term, the method we have demonstrated here could be applied to other quantum platforms (consisting of fermions or bosons) where nonlinear behaviour may be more readily exploited.

Methods

The photon pairs are generated in a 2 mm thick, nonlinear bismuth borate BiB_3O_6 (BiBO) crystal phase matched for non-collinear type-I spontaneous parametric downconversion, pumped by a 60 mW 404 nm continuous wave diode laser. The photons are spectrally filtered using 2 nm full width at half maximum interference filters centred on 808 nm and collected with aspheric lenses focusing on polarisation maintaining fibres (PMFs). The typical two-photon count rate directly from the source with two 60% efficient single photon counting modules (SPCMs) is 50 kHz. For a coherent input state, arrival time of the two photons at the input of the waveguide array is made identical via characterisation by performing a Hong-Ou-Mandel experiment¹. The polarisation state $|D\rangle = (|H\rangle + |V\rangle)/\sqrt{2}$ is then prepared for both photons using a half wave-plate with optic axis set to $\pi/8$ radians. The polarisation in the left arm is matched and purified to that of the right using a rotated polarisation beam splitter in transmission. The two photon state launched into the waveguide array is then $(|H\rangle_j + |V\rangle_j)(|H\rangle_k + e^{i(\phi+\epsilon)}|V\rangle_k)/2$. The collecting PMF and the birefringence of the waveguide array preserve horizontal and vertical polarisation components for both photons and prohibit crosstalk between horizontal and vertical light; PMF-coupled polarisation beam splitters at the output of the waveguide array allow two-photon correlated detections across the two orthogonal polarisations to project the initial input state to be the entangled state $(|H\rangle_j|V\rangle_k + e^{i(\phi+\epsilon)}|V\rangle_j|H\rangle_k)/\sqrt{2}$; the extra phase ϵ is compensated using a $Z(0)$ rotation on the right arm of the photon source comprised of two quarter waveplates (optic axis at $\pi/4$ radians) with a half waveplate between (optic axis at $-(\pi+\phi+\epsilon)/4$ radians, see Fig. 1 of the main text).

The waveguide array was fabricated from silicon oxynitride (SiON) thin films were grown by plasma enhanced chemical vapour deposition (PECVD) onto thermally oxidised $\langle 100 \rangle$ oriented 100-mm silicon wafers applying an Oxford 80 Plasmalab Systems. A deposition process based on 2% SiH_4/N_2 and N_2O was performed at 60 W power, 187.5 kHz frequency, 650 mTorr pressure and 300°C substrate temperature. The SiON films were annealed for 3 hours at 1150°C in a nitrogen atmosphere. By optical inspection at 632 nm wavelength a film thickness of $d = 603 (\pm 3)$ nm and a refractive index (for TE) of $n_{\text{TE}} = 1.5232 (\pm 1 \times 10^{-3})$ were measured. The channel waveguides were obtained from standard lithography followed by reactive ion etching in CHF_3/O_2 chemistry at 350 W plasma power. The etch depth ($d = 613 \pm 5$ nm) was confirmed by profilometry. A 5- μm thick upper cladding layer was deposited in two steps applying a Low Pressure CVD TEOS-process and standard PECVD SiO_2 deposition. The upper cladding was annealed at 1150°C for 3 hours. For a core width of 1.8- μm the total birefringence of the waveguide, including material and form birefringence³⁴, is of the order $\Delta n = n_{\text{TM}} - n_{\text{TE}} = 2 \times 10^{-4}$. This value provides polarization preserving propagation for the TE and TM photons throughout the device. Moreover, the birefringence is small enough to ensure a nearly identical mode overlap, and coupling ratio, between different waveguides in the coupled array for TM and TE modes. This implies that the processes $A^a = A^{\text{TE}}$ and $A^b = A^{\text{TM}}$ are matched, as required and verified in the reported experiment. The coupled waveguide arrays were accessed with lithographically patterned bends (minimum bend radius of 600 μm) that gradually mapped the 250 μm pitched input (for 250 μm pitched PMF array access) to the 2.8 μm pitch in the evanescent coupling region. The coupling region is

350 μm long, before bending gradually to an output pitch of 125 μm which was accessed by 250 μm pitched arrays of PMF; the output measurements were alternated between access to all odd labeled waveguides and all even labeled waveguides. The optical chips were diced from the wafer.

Acknowledgements

This work was supported by EPSRC, ERC, US AFOSR, NSQI and European projects PHORBITECH, QUANTIP. J.C.F.M. is supported by a Leverhulme Trust Early Career Fellowship. A.P. holds a Royal Academy of Engineering Research Fellowship. J.L.O.B. acknowledges a Royal Society Wolfson Merit Award and a Royal Academy of Engineering Chair in Emerging Technologies.

Author contributions

J.C.F.M., K.P., J.D.A.M. and A.P. contributed equally to writing this manuscript and conducting the experiment. All authors reviewed the manuscript.
